Abstract

This paper develops a method for estimating parameters of a vector autoregression (VAR) observed in white noise. The estimation method assumes the noise variance matrix is known and does not require any iterative process. This study provides consistent estimators and shows the asymptotic distribution of the parameters required for conducting tests of Granger causality. Methods in the existing statistical literature cannot be used for testing Granger causality, since under the null hypothesis the model becomes unidentifiable. Measurement error effects on parameter estimates were evaluated by using computational simulations. The results show that the proposed approach produces empirical false positive rates close to the adopted nominal level (even for small samples) and has a good performance around the null hypothesis. The applicability and usefulness of the proposed approach are illustrated using a functional magnetic resonance imaging dataset.

Key Words: Asymptotic property, errors-in-variables model, Granger causality, multivariate analysis.

1 INTRODUCTION

Multivariate time series modeling is an important component for the quantitative assessment of relationships between variables in many applied areas. This issue is essential in financial applications, for example, enabling optimal portfolio allocation, setting trading strategies over sectors of the market, or exchanging rates (Sims, 1980; Ni and Sun, 2003). In addition, the vector autoregressive model (VAR) is widely used in many fields such as economics (Granger, 1969), geophysics (Liu and Rodríguez, 2005), bioinformatics (Fujita et al., 2007a) and neuroscience (Goebel et al., 2003).

The main reasons for the attractiveness of the VAR model in applied areas are its simplicity and relation with the concept of Granger causality (Granger, 1969). Granger causality has become a prominent concept in connectivity networks modeling, because it provides inferences about the direction of information flow between different time series. Several studies in biological systems emphasize the importance of identification and description of gene regulator networks (Gottesman, 1984; Kato, 2007), mainly in the study of tumors or structural diseases. Mukhopadhyay and Chatterjee (2007); Fujita et al. (2007a,b) introduced the utilization of VAR-based models to study these issues by applying these models to gene expression datasets. In Neuroscience, the *functional integration* theories highlight that brain functions heavily depend on neural connectivity networks (Cohen and Tong, 2001). Several neuroimaging studies (Goebel et al., 2003; Sato et al., 2006; Abler et al., 2006) suggested that VAR models and Granger causality are suitable to identify the information flow between neural structures. Nevertheless, it is well known that most biological measurements are subject to error, since the precision of acquisition equipments is never absolute. Actually, this limitation is present in most studies involving experimental data, such as chemistry, physics, biometrics, etc.

Although technically incorrect, the most common procedure is simply to ignore the measurement errors, i.e.: assume that the variables of interest are the observed variables. It is important to highlight that this assumption has serious implications. The utilization of conventional VAR model in this case would not identify correctly the relationships between the variables of interest (latent variables). It happens because the model white noise will not be independent which leads to misestimations of the model parameters. The usual assumption is acceptable when the errors are negligible. However, it is known that due to acquisition processes limitations, the measurement errors in biology (e.g.: gene expressions or brain signals) are not negligible. In these cases, the utilization of conventional VAR models may result in biased parameter estimation and as a consequence, unreliable Granger causality detection.

In the following, we define the usual VAR model (for a more detailed description, see for instance, Lütkepohl, 2005). Let $\mathbf{z}_t = (z_{1t}, \dots, z_{pt})^\top$ denotes a $(p \times 1)$ vector of time series variables. The usual VAR(r) model has the form

$$\mathbf{z}_t = \mathbf{a} + \mathbf{B}_1 \mathbf{z}_{t-1} + \dots + \mathbf{B}_r \mathbf{z}_{t-r} + \mathbf{q}_t, \quad t = 1, \dots, n \quad (1)$$

where n is the sample size, $\mathbf{B}_j$ for $j = 1, \dots, r$ are $(p \times p)$ coefficient matrices and $\mathbf{q}_t$ is a $(p \times 1)$ unobservable zero mean white noise vector process with covariance

matrix Σ . For convenience, we consider that $\mathbf{z}_l = \mathbf{0}$ for all $l \leq 0$. We are assuming throughout this paper that model (1) satisfies the stability condition defined in Lütkepohl (2005) on page 12. Therefore, under stationarity conditions, the mean and the autocovariance function are given, respectively, by

$$E(\mathbf{z}_t) = \boldsymbol{\mu}_z = \left(\mathbf{I}_p - \sum_{j=1}^r \mathbf{B}_j \right)^{-1} \mathbf{a},$$

$$\boldsymbol{\gamma}(h) = E[(\mathbf{z}_t - \boldsymbol{\mu}_z)(\mathbf{z}_{t-h} - \boldsymbol{\mu}_z)^\top] = \sum_{j=1}^r \mathbf{B}_j \boldsymbol{\gamma}(h-j), \quad \text{for } h = 1, 2, 3, \dots$$

and

$$\boldsymbol{\gamma}(0) = \sum_{j=1}^r \mathbf{B}_j \boldsymbol{\gamma}(-j) + \Sigma$$

where $\mathbf{I}_p$ denotes the $p \times p$ identity matrix and $\boldsymbol{\gamma}(-j) = \boldsymbol{\gamma}(j)^\top$.

Model (1) can be written in short as

$$\mathbf{z}_t = \mathbf{a} + \mathbf{B} \mathbf{z}_{t-1}^* + \mathbf{q}_t, \quad t = 1, \dots, n \quad (2)$$

where $\mathbf{B} = (\mathbf{B}_1 \ \mathbf{B}_2 \ \dots \ \mathbf{B}_r)$ is a $p \times pr$ matrix and $\mathbf{z}_{t-1}^* = (\mathbf{z}_{t-1}^\top, \mathbf{z}_{t-2}^\top, \dots, \mathbf{z}_{t-r}^\top)^\top$.

Therefore, if the white noise has normal distribution, the conditional Maximum Likelihood (ML) estimators of $\mathbf{a}$, $\mathbf{B}$ and Σ are equal to the ordinary least squares estimators. They are given, respectively, by

$$\hat{\mathbf{a}}_{ML} = \bar{\mathbf{z}}_t - \hat{\mathbf{B}}_{ML} \bar{\mathbf{z}}_{t-1}^*, \quad \hat{\mathbf{B}}_{ML} = (\mathbf{S}_{\mathbf{z}_{t-1}^*}^{-1} \mathbf{S}_{\mathbf{z}_{t-1}^* \mathbf{z}_t})^\top \quad \text{and} \quad \hat{\Sigma}_{ML} = n^{-1} \sum_{i=1}^n \hat{\mathbf{q}}_i \hat{\mathbf{q}}_i^\top \quad (3)$$

where $\bar{\mathbf{z}}_{t-1}^* = n^{-1} \sum_{i=1}^n \mathbf{z}_{i-1}^*$, $\bar{\mathbf{z}}_t = n^{-1} \sum_{i=1}^n \mathbf{z}_i$, $\hat{\mathbf{q}}_i = \mathbf{z}_i - \hat{\mathbf{a}}_{ML} - \hat{\mathbf{B}}_{ML} \mathbf{z}_{i-1}^*$, $\mathbf{S}_{\mathbf{z}_{t-1}^*} = n^{-1} \sum_{i=1}^n (\mathbf{z}_{i-1}^* - \bar{\mathbf{z}}_{t-1}^*) (\mathbf{z}_{i-1}^*)^\top$ and $\mathbf{S}_{\mathbf{z}_{t-1}^* \mathbf{z}_t} = n^{-1} \sum_{i=1}^n (\mathbf{z}_{i-1}^* - \bar{\mathbf{z}}_{t-1}^*) \mathbf{z}_i^\top$.

The consistence of those conditional ML estimators is assured under the stationary conditions (see Lütkepohl, 2005, for further details). The consistence is shown using the fact that

$$\bar{\mathbf{z}}_t \xrightarrow{\mathcal{P}} \boldsymbol{\mu}_z, \quad \bar{\mathbf{z}}_{t-1}^* \xrightarrow{\mathcal{P}} \boldsymbol{\mu}_{z^*} = \mathbf{1}_r \otimes \boldsymbol{\mu}_z, \quad \mathbf{S}_{\mathbf{z}_{t-1}^*} \xrightarrow{\mathcal{P}} \Gamma_r(0) \quad \text{and} \quad \mathbf{S}_{\mathbf{z}_{t-1}^* \mathbf{z}_t} \xrightarrow{\mathcal{P}} \Gamma_r(0) \mathbf{B}^\top$$

where “ $\xrightarrow{\mathcal{P}}$ ” denotes convergence in probability when the sample size increases, $\otimes$ denotes the Kronecker product, $\mathbf{1}_r$ is a r -dimensional column vector of ones, and

the covariance function of $\mathbf{z}_{t-1}^*$ is given by

$$\begin{aligned}\mathbf{\Gamma}_r(h) &= E[(\mathbf{z}_{t-1}^* - \boldsymbol{\mu}_{\mathbf{z}^*})(\mathbf{z}_{t-h-1}^* - \boldsymbol{\mu}_{\mathbf{z}^*})^\top] \\ &= \begin{bmatrix} \gamma(h) & \gamma(h+1) & \dots & \gamma(h+r-1) \\ \gamma(h-1) & \gamma(h) & \dots & \gamma(h+r-2) \\ \vdots & \vdots & \ddots & \vdots \\ \gamma(h-r+1) & \gamma(h-r+2) & \dots & \gamma(h) \end{bmatrix}.\end{aligned}$$

As described previously, VAR modeling is commonly applied for detecting Granger causality relationships. The basic idea of Granger causality is the evaluation of temporal information founded on the assumption that the cause always precedes its effect (Granger, 1969). Let x_t and y_t be two time series. From the statistical perspective, x_t is said to Granger-cause y_t if the prediction error of y_t , conditioning on the past values of both series, is less than considering solely the past values of y_t . In other words, the past values of x_t contains relevant information to improve the predictions of y_t . Note that Granger causality concept is not equivalent to classical aristotelian causality, since the former is based solely on prediction errors. However, due to its simplicity, it may be applied to identify possible effective causalities.

One possible approach of using VAR models for Granger causality detection is by performing statistical tests on $\mathbf{B}_j$'s coefficients. Considering y_t equation, if there is at least one coefficient multiplying the past values of x_t which is not equal to zero, then x_t is said to Granger-cause y_t . Thus, this procedure involves the estimation of $\mathbf{B}_j$, their respective covariance matrices, and the application of hypothesis testing.

In general, many physical, biological and chemical variables have the measurement process subject to random effects and it is very common analyze them by using models assuming that these measurement errors are negligible. It may bring up undesirable features as biased estimates as well as their standard errors and, as a consequence, dangerously false confidence intervals and hypotheses testing will often be obtained using such approach. Thus, it is necessary to consider the measurement error on the modeling of these type of time series.

In this paper, we study a VAR model with main concern on including measurement errors. Let $\mathbf{z}_t$ be the true variable that is not directly observed, instead a substitute variable $\mathbf{Z}_t$ is observed which has an additive structure given by

$$\mathbf{Z}_t = \mathbf{z}_t + \mathbf{e}_t, \quad t = 1, \dots, n \quad (4)$$

where $\mathbf{Z}_t = (Z_{1t}, Z_{2t}, \dots, Z_{pt})^\top$ is the observed vector and $\mathbf{e}_t = (e_{1t}, e_{2t}, \dots, e_{pt})^\top$ is the measurement error vector with mean zero and variance-covariance matrix $\boldsymbol{\Sigma}_e$.

In most cases, if the usual conditional ML estimator is adopted for the observations subject to errors, i.e., replacing $\mathbf{z}_t$ with $\mathbf{Z}_t$ in the equation (1), the estimator of $\mathbf{B}$ will be biased (as can be seen in (6)). Therefore, in order to overcome this limitation the measurement errors should be included in the estimation procedure. Nevertheless, the model (1) with the equation (4) is not identifiable, since the covariance matrices of $\mathbf{q}_t$ and $\mathbf{e}_t$ are confounded when $\mathbf{B} = \mathbf{0}$. It is easy to see that in the univariate AR(1), note that when $r = p = 1$ and $b = 0$ we have: $Z_i = a + q_i + e_i$ with $E(Z_i) = a$, $\gamma(0) = \sigma^2 + \sigma_e^2$ and $\gamma(h) = 0$ for all $h \neq 0$. It is impossible to estimate σ^2 and σ_e^2 separately by observing only $Z_1, \dots, Z_n$. This problem can be avoided by using previous knowledge about the variance of $\mathbf{e}_t$.

This paper is organized as follows. Section 2 proposes consistent estimators for the VAR model with measurement errors and also presents the asymptotic distribution of the estimator of the elements of $\mathbf{B}$. In Section 3, simulation studies are undertaken to investigate some aspects of the proposed estimators (rejection rates for a test of hypothesis, biases and mean square errors) also it is verified the impact by erroneously considering the usual model. We applied the models in a functional magnetic resonance imaging dataset in Section 4 and we finish the paper with conclusions and remarks in Section 5.

2 VAR WITH MEASUREMENT ERRORS

In the presence of measurement errors, the conventional ML estimation of VAR models produces biased estimators and they can lead to wrong statistical inference (see Fuller, 1987, in which it is found a discussion over errors-in-variables in regression models). There are some studies about measurement errors in times series (e.g., Geweke, 1977; Aigner et al., 1984). Those studies use Kalman filtering methodology and an Expectation and Maximization algorithm that requires intensive iterative procedures. Maravall and Aigner (1977) have provided a careful expose of the identifiability of some time series models with errors in variables. Beck (1990) describes approaches based on state space modeling and Kalman filtering and demonstrates the usefulness of these tools in dynamic models. Kellstedt et al. (1996) show the efficiency gains adopting an errors-in-variables model, and the precision of Kalman filter estimates in the face of autocorrelation. These measurement techniques have been applied to a variety of substantive problems, including dynamic representation, social problems (such as racial inequality), monetary policy and public entrepreneur-

ship (**Citar**).

These state space models can be attractive alternatives to conventional VAR modeling. However, in practice, the implementation of the estimators are not described in analytical form, but by interactive algorithms or numerical optimization solutions. In addition, the derivation of estimators convergence, standard errors, consistence and asymptotic distribution may be complex in these cases. In Shumway and Stoffer (2000), the section on state space methods shows an alternative procedure for how to estimate $\mathbf{B}$, $\mathbf{\Sigma}$ and $\mathbf{\Sigma}_e$ under model (1) with the error equations (4), using the EM algorithm. Hannan et al. (2003) proposed another iterative procedure to estimate these parameters. Nevertheless, as the main goal of this paper is to test Granger causality, these approaches can not be used, since the model becomes unidentifiable under the hypothesis $\mathbf{B} = \mathbf{0}$.

In this study, we provide simple and closed forms for the estimators when $\mathbf{\Sigma}_e$ is known, which allows the direct derivation of their respective asymptotic properties. Since the main concern of several practical applications is Granger causality testing, this information is essential to data analysis. In this section, the main concern is the parameter estimation and its asymptotic properties. Theorem 1 states consistent estimators for the model parameters and Theorem 2 establishes the asymptotic distribution for the estimator of $\text{vec}(\mathbf{B}^\top)$ given in Theorem 1, where $\text{vec}(\mathbf{C})$ is an operator that heaps the columns of the matrix $\mathbf{C}$.

The methodology presented in this section is based on correcting the asymptotic bias of conventional ML estimator caused by the measurement error effect. The outcome is a consistent estimator with good asymptotic properties such as normality. The estimators and the asymptotic covariance matrix for the proposed estimator of $\text{vec}(\mathbf{B}^\top)$ are computed easily and no iterative procedure is required. We must remark that those estimators are not the conditional ML estimators nor the ML estimators taking into account the measurement errors which are very complicated to reach by maximizing the likelihood, even under normality of the errors.

Theorem 1. *If $\mathbf{e}_t \sim \mathcal{N}(\mathbf{0}, \mathbf{\Sigma}_e)$ with $\mathbf{\Sigma}_e$ known. Then, the parameters of the model (1) under measurement errors as in (4) have consistent estimators given by*

$$\hat{\mathbf{a}} = \bar{\mathbf{Z}}_t - \hat{\mathbf{B}}\bar{\mathbf{Z}}_{t-1}^*, \quad \hat{\mathbf{B}} = \left[(\mathbf{S}_{\mathbf{Z}_{t-1}^*} - \mathbf{I}_r \otimes \mathbf{\Sigma}_e)^{-1} \mathbf{S}_{\mathbf{Z}_{t-1}^*} \mathbf{z}_t \right]^\top \quad (5)$$

and

$$\widehat{\Sigma} = n^{-1} \sum_{i=1}^n (\mathbf{Z}_i - \widehat{\mathbf{a}} - \widehat{\mathbf{B}} \mathbf{Z}_{i-1}^*) (\mathbf{Z}_i - \widehat{\mathbf{a}} - \widehat{\mathbf{B}} \mathbf{Z}_{i-1}^*)^\top - \Sigma_e - \widehat{\mathbf{B}} (\mathbf{I}_r \otimes \Sigma_e) \widehat{\mathbf{B}}^\top$$

where $\bar{\mathbf{Z}}_{t-1}^* = n^{-1} \sum_i \mathbf{Z}_{i-1}^*$, $\bar{\mathbf{Z}}_t = n^{-1} \sum_i \mathbf{Z}_i$, $\mathbf{S}_{\mathbf{Z}_{t-1}^*} = n^{-1} \sum_i (\mathbf{Z}_{i-1}^* - \bar{\mathbf{Z}}_{t-1}^*) \mathbf{Z}_{i-1}^{*\top}$ and $\mathbf{S}_{\mathbf{Z}_{t-1}^* \mathbf{Z}_t} = n^{-1} \sum_i (\mathbf{Z}_{i-1}^* - \bar{\mathbf{Z}}_{t-1}^*) \mathbf{Z}_i^\top$.

The proof of Theorem 1 can be found in Appendix A.1. Notice that, if $\Sigma_e = \mathbf{0}_{p \times p}$, that is, when there is no measurement error, then the estimators of Theorem 1 become the conditional ML estimators presented in (3). Also, it can be seen that the conditional ML estimator of $\mathbf{B}$ from the model (1), without considering the errors (4), is given by

$$\widehat{\mathbf{B}}_{ML} = \left[\mathbf{S}_{\mathbf{Z}_{t-1}^*}^{-1} \mathbf{S}_{\mathbf{Z}_{t-1}^* \mathbf{Z}_t} \right]^\top,$$

which is not consistent, since

$$\widehat{\mathbf{B}}_{ML} \xrightarrow{\mathcal{P}} \mathbf{B} [\mathbf{I}_{pr} + (\mathbf{I}_r \otimes \Sigma_e) \Gamma_r(0)^{-1}]^{-1}. \quad (6)$$

The main steps to demonstrate (6) is given in Appendix A.1, in which is sufficient to compute the limit of $\mathbf{S}_{\mathbf{Z}_{t-1}^*}$ and $\mathbf{S}_{\mathbf{Z}_{t-1}^* \mathbf{Z}_t}$. The quantity $\mathbf{S}_{\mathbf{Z}_{t-1}^*}$ has two sources of variations, one that refers to the unobservable variable $\mathbf{z}_{t-1}^*$ and another one that refers to the measurement error. If the measurement error is huge and the sample size is not large enough, the quantity $(\mathbf{S}_{\mathbf{Z}_{t-1}^*} - \mathbf{I}_r \otimes \Sigma_e)$ may not be positive definite and the estimator $\widehat{\mathbf{B}}$, presented in (5), will be inadmissible. If the quantity $(\mathbf{S}_{\mathbf{Z}_{t-1}^*} - \mathbf{I}_r \otimes \Sigma_e)$ has at least one eigen value close to zero the estimator $\widehat{\mathbf{B}}$, presented in 5, will be unstable (because the computation of a matrix inverse requires all eigen values to be different from zero). If the matrix Σ_e is well specified, one way to avoid such inadmissibility and instability is increasing the sample size.

In many practical applications, there is some interest on testing some elements of the matrix $\mathbf{B}$ (e.g., the so called Granger causality test). However, the exact distribution of $\text{vec}(\widehat{\mathbf{B}}^\top)$ is hard to compute. Thus, one can use its asymptotic distribution to build confidence regions and hypothesis testing as an approximation when the sample size is finite. The Theorem below gives us the asymptotic distribution of $\text{vec}(\widehat{\mathbf{B}}^\top)$.

Theorem 2. *If $\mathbf{e}_t \sim \mathcal{N}(\mathbf{0}, \Sigma_e)$ with Σ_e known and $E(q_{ij_1} q_{ij_2} q_{ij_3} q_{ij_4}) < \infty$ for all $j_1, j_2, j_3, j_4 \in \{1, \dots, p\}$, where q_{ij} is the j^{th} element of $\mathbf{q}_i$. Then, the asymptotic distribution of $\text{vec}(\widehat{\mathbf{B}}^\top)$ obtained in Theorem 1 is given by*

$$\sqrt{n}(\text{vec}(\widehat{\mathbf{B}}^\top) - \text{vec}(\mathbf{B}^\top)) \xrightarrow{D} \mathcal{N}(\mathbf{0}, \mathbf{\Phi}), \quad (7)$$

where the $p^2r \times p^2r$ matrix $\mathbf{\Phi}$ is given by

$$\mathbf{\Phi} = \mathbf{\Sigma}_\vartheta \otimes \mathbf{\Gamma}_r(0)^{-1} + (\mathbf{I}_p \otimes \mathbf{\Gamma}_r(0)^{-1}) \mathbf{A}_r (\mathbf{I}_p \otimes \mathbf{\Gamma}_r(0)^{-1})$$

where

$$\begin{aligned} \mathbf{A}_r = & \mathbf{\Sigma}_\vartheta \otimes (\mathbf{I}_r \otimes \mathbf{\Sigma}_e) + \mathbf{B}^\top \otimes [\mathbf{\Sigma}_e \mathbf{B} (\mathbf{I}_r \otimes \mathbf{\Sigma}_e)] + \\ & - \sum_{h=1}^r \left\{ (\mathbf{B}_h \mathbf{\Sigma}_e) \otimes \mathbf{\Gamma}_r(h) + (\mathbf{\Sigma}_e \mathbf{B}_h^\top) \otimes \mathbf{\Gamma}_r(-h) \right\} + \\ & + \sum_{h=1-r}^{r-1} [\mathbf{B}(\mathbf{J}_{-h} \otimes \mathbf{\Sigma}_e) \mathbf{B}^\top] \otimes \mathbf{\Gamma}_r(h). \end{aligned}$$

and $\mathbf{\Sigma}_\vartheta = \mathbf{\Sigma} + \mathbf{\Sigma}_e + \mathbf{B}(\mathbf{I}_r \otimes \mathbf{\Sigma}_e) \mathbf{B}^\top$, where $\mathbf{J}_l$ is a $(r \times r)$ matrix of zeros with one's in the $|l|^{th}$ diagonal above (below) the main diagonal if $l > 0$ ($l < 0$) and $\mathbf{J}_0$ is a $(r \times r)$ matrix of zeros.

The proof of Theorem 2 can be seen in Appendix A.2. For all r and $\mathbf{\Sigma}_e = 0$ we have $\mathbf{\Phi} = \mathbf{\Sigma} \otimes \mathbf{\Gamma}_r(0)^{-1}$, as given in Lütkepohl (2005). The normal distribution assumption for the measurement error is required to compute the expectation of polynomial functions (until forth degrees) of the elements of $\mathbf{e}_t$. Notice that, if $r = 1$ we have the VAR(1) model and the asymptotic covariance simplifies to

$$\mathbf{\Phi} = \mathbf{\Sigma}_\vartheta \otimes \mathbf{\gamma}(0)^{-1} + (\mathbf{I}_p \otimes \mathbf{\gamma}(0)^{-1}) \mathbf{A}_1 (\mathbf{I}_p \otimes \mathbf{\gamma}(0)^{-1})$$

where

$$\mathbf{A}_1 = \mathbf{\Sigma}_\vartheta \otimes \mathbf{\Sigma}_e + \mathbf{B}^\top \otimes (\mathbf{\Sigma}_e \mathbf{B} \mathbf{\Sigma}_e) - [(\mathbf{B} \mathbf{\Sigma}_e) \otimes (\mathbf{\gamma}(0) \mathbf{B}^\top) + (\mathbf{\Sigma}_e \mathbf{B}^\top) \otimes (\mathbf{B} \mathbf{\gamma}(0))].$$

The i^{th} element of $\text{vec}(\widehat{\mathbf{B}}^\top)$, is asymptotically normally distributed with standard error given by the square root of i^{th} diagonal element of $\mathbf{\Phi}$. Thus, we can obtain hypotheses tests on the individual coefficients, or more general form of contrasts

$$H_0 : \mathbf{C} \text{vec}(\mathbf{B}^\top) = \mathbf{d} \quad \text{Versus} \quad H_1 : \mathbf{C} \text{vec}(\mathbf{B}^\top) \neq \mathbf{d},$$

which involves coefficients across different equations of the VAR model. Thus, Granger causality testing can be carried out by adequately specifying this contrasts matrix. An illustrative example is the case of series x_t and y_t , in which we

are interested in evaluating the Granger causality from x_t to y_t in an r -order VAR model. The matrix $\mathbf{C}$ has r rows, one for each coefficient related to the past values of x_t in the y_t equation. Considering that each column of $\mathbf{C}$ refers to each VAR coefficient, the contrast matrix is specified by simply setting 1 to the cell at the respective column and row for the x_t coefficients in y_t equation. This may be tested using the Wald-type statistic conveniently expressed as

$$n(\mathbf{C}\text{vec}(\hat{\mathbf{B}}^\top) - \mathbf{d})^\top [\mathbf{C}\Phi\mathbf{C}^\top]^{-1}(\mathbf{C}\text{vec}(\hat{\mathbf{B}}^\top) - \mathbf{d}) \quad (8)$$

Under the null hypotheses, (8) has a $\chi^2(m)$ distribution in the limit, where $m = \text{rank}(\mathbf{C})$ gives the number of linear restrictions.

The above study can also be developed to the intercept model estimator, it can be found by applying the delta method (Lehmann and Casella, 1998) in the asymptotic distribution of $(\bar{\mathbf{Z}}_t^\top, \bar{\mathbf{Z}}_{t-1}^{*\top}, \text{vec}(\hat{\mathbf{B}}^\top)^\top)$, since $\hat{\mathbf{a}} = \bar{\mathbf{Z}}_t - (\mathbf{I} \otimes \bar{\mathbf{Z}}_{t-1}^{*\top})\text{vec}(\hat{\mathbf{B}}^\top)$. Although, this asymptotic distribution is important to test hypotheses regarding the model intercept, it is outside the main scope of this article and does not have any impact on the Granger causality, for this reason we skip it.

3 SIMULATION RESULTS

In this section we conduct some simulation studies in order to evaluate the adequacy of the asymptotic distribution of $\text{vec}(\hat{\mathbf{B}}^\top)$ for small and moderate samples sizes. Computations were performed using the software R (www.r-project.org).

For each setup of parameters and sample sizes, we considered 15,000 Monte Carlo samples generated from a VAR(1) model with measurement errors, given by

$$\begin{pmatrix} z_{1,t} \\ z_{2,t} \end{pmatrix} = \begin{pmatrix} a_1 \\ a_2 \end{pmatrix} + \begin{bmatrix} b_{11} & b_{12} \\ b_{21} & b_{22} \end{bmatrix} \begin{pmatrix} z_{1,t-1} \\ z_{2,t-1} \end{pmatrix} + \begin{pmatrix} q_{1t} \\ q_{2t} \end{pmatrix}, \quad (9)$$

$$\begin{pmatrix} Z_{1,t} \\ Z_{2,t} \end{pmatrix} = \begin{pmatrix} z_{1,t} \\ z_{2,t} \end{pmatrix} + \begin{pmatrix} e_{1t} \\ e_{2t} \end{pmatrix}. \quad (10)$$

In all samples, we have considered the following setup of parameters: $a_1 = a_2 = 1$, $b_{11} = b_{22} = 0.5$,

$$\Sigma = \begin{bmatrix} 10 & 5 \\ 5 & 5 \end{bmatrix},$$

where the vector parameters values of (b_{12}, b_{21}) were the values of the set $\{(b_{12}, b_{21}); b_{12} \in S \text{ and } b_{21} \in S\}$, where $S = \{-0.4, -0.2, 0.0, 0.2, 0.4\}$, the variance of the measurement error $\mathbf{e}_t$ was $\Sigma_e = 2\mathbf{I}_2$, and the size samples $n = 50, 100, 250, 500$.

The rejection rates of the hypothesis $H_0 : b_{12} = b_{21} = 0$ (i.e., $z_{2,t-1}$ does not help to explain $z_{1,t}$ and $z_{1,t-1}$ does not help to explain $z_{2,t}$) are shown in Table 1, in which the test sizes are the rejection rates under the null hypothesis (that appears in bold). The Wald-type statistics (8) is used at 5% nominal level. From this table we have that, the test sizes from the proposed model are closer to the nominal level (5%) as compared to the usual approach for all sample sizes. Furthermore, when n increases the test sizes for the usual model also increase and, consequently, they do not converge to the adopted nominal level. This is a somewhat expected behavior because the usual approach produces biased estimates and standard errors. Table 1 depicts the power of the test in each methodology, which shows a good performance of the proposed approach. Nevertheless, it is not possible to compare the power between the two methods because they have different empirical test sizes.

[[Table 1]]

We observe that, the results shown in Table 1 are similar for other values of the parameters $\mathbf{a}$ and $\mathbf{B}$, if we maintain the same proportionality of Σ and Σ_e as defined above. But, our simulations suggest that the larger the measurement error, the larger the sample size required to have a good asymptotic approximation for the Wald-type statistics (8).

We also conduct simulation studies for testing the simple hypothesis $H_0 : b_{12} = 0$ at 5% nominal level. In this study, we keep fixed the value of $b_{21} = 0.2$. Others simulations were built considering others values for b_{21} , however, the results are close to each other and, for this reason, we omit them. As can be seen, Tables 1 and 2 present similar behaviors, i.e., the proposed model has always empirical size test closer to the nominal level than the usual model.

[[Table 2]]

In Table 1 and 2, the usual approach seems to be most powerful than the proposed approach when $b_{21} = 0.2$ and $b_{21} = 0.4$. However, as aforementioned, they can not be compared directly, just because the real nominal level used to compute that powers are not the same. Thus, we used a descriptive measure in order to analyze both methodologies around the null hypothesis. Let $a_n(\alpha)$ be the probability of the error type I using the true distribution of (8) when the sample size is n and α is the adopting nominal level based on its asymptotic distribution. For instance,

in Table 2 we have estimated $\widehat{a_{100}}(0.05) = 0.0513$ for the proposed approach and $\widehat{a_{100}}(0.05) = 0.0837$ for the usual approach. An expected behavior for good statistics is $a_n(\alpha) \xrightarrow{n \rightarrow \infty} \alpha$ which means that the quantiles of the true distribution of (8) will be close to the quantiles of the asymptotic distribution, $\chi^2(m)$, when the sample size is sufficiently large. Thus, the relation $a_n(\alpha)/\alpha$ tell us how far is the α -quantil of the asymptotic distribution from the true distribution of (8) for each n . Therefore, we can define a sort of corrected power as

$$P_n^{(c)}(\alpha) = \frac{P_n(a_n(\alpha))}{(a_n(\alpha)/\alpha)}$$

where $P_n(a(\alpha))$ is the power using the true probability of the error type I, namely $a_n(\alpha)$. We are just penalizing the power by the distance between $a_n(\alpha)$ and α . Notice that, the power under the null hypothesis has to be the nominal level and for comparing powers from different statistics it must be done using the same nominal level. Let $a_{1n}(\alpha)$ and $a_{2n}(\alpha)$ be the true probability of the error type I for two different statistics when the sample size is n . Then, under the null hypothesis, we have

$$P_{1n}^{(c)}(\alpha) = P_{2n}^{(c)}(\alpha) = \alpha,$$

and hence, the corrected powers $P_{1n}^{(c)}$ and $P_{2n}^{(c)}$ are comparable. Moreover, under an alternative hypothesis and when n increases, an expected behavior of $P_n^{(c)}(\alpha)$ is to converge to one. Although, this corrected power is not a monotonic function of the sample size nor of the nominal level, we believe that it is a kind of descriptive measure to evidence how unsuitable is the usual model when compared with the proposed one outside the null hypothesis. Furthermore, the proposed corrected power varies between 0 and infinity. Figure 1 shows the corrected power for both approaches, the null hypothesis was $H_0 : b_{12} = 0$. The full line refers to the proposed approach and the dashed line refers to the usual one. The panels (a.1), (b.1), (c.1) and (d.1) refer to the corrected power when the alternative hypothesis are $b_{12} = -0.4$, $b_{12} = -0.2$, $b_{12} = 0.2$ and $b_{12} = 0.4$, respectively at $\alpha = 0.01$. The panels (a.2), (b.2), (c.2) and (d.2) refer to the corrected power when the alternative hypothesis are $b_{12} = -0.4$, $b_{12} = -0.2$, $b_{12} = 0.2$ and $b_{12} = 0.4$, respectively at $\alpha = 0.05$. The panels (a.3), (b.3), (c.3) and (d.3) refer to the corrected power when the alternative hypothesis are $b_{12} = -0.4$, $b_{12} = -0.2$, $b_{12} = 0.2$ and $b_{12} = 0.4$, respectively at $\alpha = 0.10$. We observe in all graphs that, the usual approach has the worst performance (going to zero when the sample size increases) while the proposed one have an expected behavior

for a good statistic (going to one when the sample size increases). In general, the corrected power under the usual methodology goes to zero because the distance between $a_n(\alpha)$ and α increases much faster than the uncorrected power, $P_n(a_n(\alpha))$, when n increases. This behavior is still true for another setup of parameters.

[[Figure 1]]

[[Table 3]]

Table 3 shows that, for this set of parameters, the biases of the estimators of b_{ij} ($i, j = 1, 2$) from the proposed model is smaller than the value supplied by the usual model. Moreover, the larger the sample size, the smaller the bias and MSE under the proposed model (this does not happen for the usual approach).

4 APPLICATION

As previously described, the models with measurement errors have great relevance in applied sciences, since equipment imprecisions are inherent to data acquisition. Actually, the usual models are commonly applied ignoring these errors. Nowadays, the scientific community started to pay enough attention to the fact that these procedures may lead to spurious results. In this section, we illustrate the concepts introduced in the present study with an application embedded in Neuroscience research, with the utilization of VAR modeling for the characterization of brain networks.

The dataset explored in this application is proceeding from a functional magnetic resonance imaging (fMRI) experiment. Basically, fMRI acquisition is based on monitoring the BOLD signal (blood oxygenation level dependent) at several brain regions through time. One of the main advantages of fMRI over other imaging techniques is its non-invasive protocol and relative high spatial resolution. The BOLD signal is related to oxygen consumption and blood flow, being considered as an indirect measure of local neural activity (Logothetis et al. (2001)). Regarding this property, this signal is used to quantify and locate the brain activity in humans.

In this study, the BOLD signals at four brain regions from a subject in a resting state (eyes closed) condition were considered. The data was collected in a Siemens 3Tesla MR system (TR=1800ms, TA=900ms, TE=30ms). The selected brain regions were: left primary motor cortex (left M1), right primary motor cortex (right M1), supplementary motor area (SMA) and right cerebellum. The anatomical location of this areas is shown in Figure 2. These areas are frequently involved in active and planned right hand fingertapping. We aim to evaluate the information flow

between these areas in a resting state condition by using VAR models for Granger causality identification.

A well described limitation inherent to all fMRI acquisition is the high level of scanner noise. Thus, the signals observed mirror not only the physiological variations but also includes measurement errors. For this specific dataset, it was estimated that the error composed approximately 34.60% of the observed time series standard deviation. For simplicity, each observed series were normalized to have mean zero and variance one. Thus, the measurement error was considered to be serially uncorrelated, independent of the latent variables and with a standard deviation of 0.346.

The model considered for the latent variable is given by

$$\mathbf{z}_t = \mathbf{a} + \mathbf{B}_1 \mathbf{z}_{t-1} + \mathbf{q}_t, \quad t = 1, \dots, n \quad (11)$$

where $n = 200$ is the time series length, $\mathbf{z}_t = (z_{1t}, z_{2t}, z_{3t}, z_{4t})^\top$ with z_{1t} : the *Left M1* BOLD signal, z_{2t} : the *SMA* BOLD signal, z_{3t} : the *Right M1* BOLD signal and z_{4t} : the *Right cerebellum* BOLD signal; $\mathbf{B}_1$ is the (4×4) autoregressive coefficients matrix

$$\mathbf{B}_1 = \begin{pmatrix} b_{11} & b_{12} & b_{13} & b_{14} \\ b_{21} & b_{22} & b_{23} & b_{24} \\ b_{31} & b_{32} & b_{33} & b_{34} \\ b_{41} & b_{42} & b_{43} & b_{44} \end{pmatrix}, \quad (12)$$

and $\mathbf{q}_t$ is an (4×1) unobservable zero mean white noise vector. The observed variables are given by

$$\mathbf{Z}_t = \mathbf{z}_t + \mathbf{e}_t, \quad t = 1, \dots, n \quad (13)$$

where $\mathbf{Z}_t = (Z_{1t}, Z_{2t}, Z_{3t}, Z_{4t})^\top$ and $\mathbf{e}_t = (e_{1t}, e_{2t}, e_{3t}, e_{4t})^\top$ is the measurement error vector.

The time series plots corresponding to the respective observed BOLD signal at each brain region are represented in Figure 3. Since we are interested in identifying the links of connectivity networks using Granger causality, the statistical inferences are related to the parameters b_{ij} ($i, j = 1, 2, 3, 4$). If $b_{ij} \neq 0$, then there is a information flow from brain area j to area i (Baccala and Sameshima (2001)). The coefficient estimates, standard errors and p-values ($H_0 : b_{ij} = 0$ vs $H_1 : b_{ij} \neq 0$) for both usual and proposed approaches are shown in Tables 4 and 5, respectively.

[[Figure 2]]

[[Figure 3]]

[[Figure 4]]

[[Figure 5]]

[[Table 4]]

[[Table 5]]

The results described in Tables 4 and 5 suggest the existence of bidirectional information flow between Left M1 and Cerebellum. However, the application of usual approach indicates also that Left M1 sends information to SMA and Right M1, and that the latter sends to SMA. For both usual and proposed approaches, the diagrams of the networks at the significance level of 5% are shown in Figure 4. As highlighted by the simulations results, the utilization of usual VAR estimation, ignoring the measurement errors, may result in wrong test nominal sizes. In this context, it is important to mention that the main differences between the usual and proposal results were on standard deviation estimates. Further, the proposal estimates are almost twice the values resulting from usual approach. The theory and simulations suggest the existence of biases in the latter. Consequently, the p-values from the usual method tend to be underestimated, resulting in high rejection rates. Note that this connections may possibly exist, but since the nominal level of the test is “incorrect”, the type I Error is not under control. In addition, note that some coefficients were considerably underestimated, for example b_{11} , b_{22} and b_{33} . Finally, the qq-plots represented in Figure 5 suggest that the probability density of residuals $\mathbf{Z}_t - \hat{\mathbf{Z}}_t$ are reasonably approximated by the Normal distribution.

Some studies (Biswal et al (1995)) suggest the existence of functional networks between motor areas even in resting state condition. These studies are based on correlation analysis between the BOLD signal at different brain sites. First, it is important to note that Granger causality is conceptually different from correlation, which is symmetric (it does not provide the direction of information flow), evaluated in a pairwise fashion (and not in the full multivariate sense) and it does not take into account temporal information. In fact, correlation analysis is more closely related to instantaneous Granger Causality concept, which can be useful to quantify simultaneity between time series but it is unsuitable in the context of information flow detection. Second, the usual correlation analysis does not consider the presence of measurement errors, which may also affect the statistical significance of results. The nature of functional networks in resting state is still unclear and is the subject

of several studies (Long et al. (2008)). Nevertheless, we have demonstrated in this study that the inclusion of measurement errors can considerably influence the final results. Thus, the development of novel approaches dealing with this artifact is necessary.

In summary, since the proposal and usual results differ, we conclude that the presence of measurement error cannot be ignored. An adequate treatment for this artifact is essential for the adequate description and modeling of brain networks. It is surprising that this important limitation received proper attention only recently. We believe that a preliminary analysis of this problem points toward the demand for the development of new estimation procedures regarding scanner noise characterization, physiological noise and computational implementation.

5 CONCLUSION

This paper has introduced a new approach to model multivariate times series when measurement errors are present. The simulation studies indicate that the proposed approach gives coherent results (test size close to the nominal level even for small samples, power increasing with the sample size under alternative hypotheses, biases and mean square errors decreasing when the sample size increases) under small and moderate measurement error. Such features seem no to be shared by the conventional maximum likelihood estimators which presents a much poorer performance. Furthermore, the proposal is easily attained and iterative procedures are not required. The theory, simulations and application showed that the presence of measurement error cannot be neglected and a proper model has to be considered for the adequate description and modeling of brain networks. We expect to report generalizations of the proposed model (for elliptical errors and heteroscedasticity situations), a residual study and more simulation studies for large measurement errors on incoming papers.

A PROOF OF THEOREMS

A.1 Proof of Theorem 1

In order to prove the consistence of the estimators stated in Theorem 1, namely

$$\hat{\mathbf{a}} = \bar{\mathbf{Z}}_t - \hat{\mathbf{B}}\bar{\mathbf{Z}}_{t-1}^*, \quad \hat{\mathbf{B}} = \left[(\mathbf{S}_{\mathbf{Z}_{t-1}^*} - \mathbf{I}_r \otimes \Sigma_e)^{-1} \mathbf{S}_{\mathbf{Z}_{t-1}^*} \mathbf{Z}_t \right]^\top$$

and

$$\hat{\Sigma} = n^{-1} \sum_{i=1}^n (\mathbf{Z}_i - \hat{\mathbf{a}} - \hat{\mathbf{B}}\mathbf{Z}_{i-1}^*)(\mathbf{Z}_i - \hat{\mathbf{a}} - \hat{\mathbf{B}}\mathbf{Z}_{i-1}^*)^\top - \Sigma_e - \hat{\mathbf{B}}(\mathbf{I}_r \otimes \Sigma_e)\hat{\mathbf{B}}^\top,$$

we must study the limits of the quantities $\mathbf{S}_{\mathbf{Z}_{t-1}^*}$, $\mathbf{S}_{\mathbf{Z}_{t-1}^*} \mathbf{Z}_t$, $\bar{\mathbf{Z}}_{t-1}^*$ and $\bar{\mathbf{Z}}_t^*$ when the sample size goes to infinity. Note that $\mathbf{Z}_{t-1}^* = \mathbf{z}_{t-1}^* + \mathbf{e}_{t-1}^*$, where $\mathbf{e}_{t-1}^* = (\mathbf{e}_{t-1}^\top, \dots, \mathbf{e}_{t-r}^\top)^\top$, and under the stationary conditions of a VAR(r) model we have that

$$\begin{aligned} \mathbf{S}_{\mathbf{Z}_{t-1}^*} &= n^{-1} \sum_{i=1}^n (\mathbf{Z}_{i-1}^* - \bar{\mathbf{Z}}_{t-1}^*) \mathbf{Z}_{i-1}^{*\top} \\ &= n^{-1} \sum_{i=1}^n (\mathbf{z}_{i-1}^* + \mathbf{e}_{i-1}^* - \bar{\mathbf{z}}_{t-1}^* - \bar{\mathbf{e}}_{t-1}^*) (\mathbf{z}_{i-1}^* + \mathbf{e}_{i-1}^*)^\top \\ &= \mathbf{S}_{\mathbf{z}_{t-1}^*} + \mathbf{S}_{\mathbf{e}_{t-1}^*} + O_p(n^{-1/2}) \\ &= \Gamma_r(0) + \mathbf{I}_r \otimes \Sigma_e + O_p(n^{-1/2}), \end{aligned}$$

where $\mathbf{S}_{\mathbf{e}_{t-1}^*} = n^{-1} \sum_{i=1}^n \mathbf{e}_{i-1}^* \mathbf{e}_{i-1}^{*\top}$, and $O_p(n^{-1/2})$ means limited in probability even multiplying by $n^{1/2}$ (it happens with the crossing product in the above expression). That is, $\mathbf{S}_{\mathbf{Z}_{t-1}^*} \xrightarrow{\mathcal{P}} \Gamma_r(0) + \mathbf{I}_r \otimes \Sigma_e$. Following the same scheme, we have that

$$\begin{aligned} \mathbf{S}_{\mathbf{Z}_{t-1}^*} \mathbf{Z}_t &= n^{-1} \sum_{i=1}^n (\mathbf{Z}_{i-1}^* - \bar{\mathbf{Z}}_{t-1}^*) \mathbf{Z}_i^\top \\ &= n^{-1} \sum_{i=1}^n (\mathbf{z}_{i-1}^* + \mathbf{e}_{i-1}^* - \bar{\mathbf{z}}_{t-1}^* - \bar{\mathbf{e}}_{t-1}^*) (\mathbf{z}_i + \mathbf{e}_i)^\top \\ &= \mathbf{S}_{\mathbf{z}_{t-1}^*} \mathbf{z}_t + O_p(n^{-1/2}) \\ &= \Gamma_r(0) \mathbf{B}^\top + O_p(n^{-1/2}), \end{aligned}$$

and finally, both the quantities $\bar{\mathbf{Z}}_{t-1}^*$ and $\bar{\mathbf{Z}}_t^*$ converge in probability to $\boldsymbol{\mu}^*$. Hence,

$$(\mathbf{S}_{\mathbf{Z}_{t-1}^*} - \mathbf{I}_r \otimes \Sigma_e)^{-1} \xrightarrow{\mathcal{P}} \Gamma_r(0)^{-1} \quad \text{and} \quad \mathbf{S}_{\mathbf{Z}_{t-1}^*} \mathbf{Z}_t \xrightarrow{\mathcal{P}} \Gamma_r(0) \mathbf{B}^\top,$$

thus, the probability convergence of $\hat{\mathbf{a}}$, $\hat{\mathbf{B}}$ and $\hat{\Sigma}$ to $\mathbf{a}$, $\mathbf{B}$ and Σ follow, respectively.

A.2 Proof of Theorem 2

The proof idea has three steps. The first step consists in show that $\text{vec}(\widehat{\mathbf{B}}^\top) - \text{vec}(\mathbf{B}^\top)$ can be written as linear combinations of a vectorial mean. The second one, we must demonstrate that this vectorial mean has an asymptotic normal distribution. The last step must conclude that $\text{vec}(\widehat{\mathbf{B}}^\top) - \text{vec}(\mathbf{B}^\top)$ also has an asymptotic normal distribution. In order to prove Theorem 2, we need some auxiliary results, which are exposed in two propositions below.

Proposition 1. *Under the model (1) and (4), the proposed estimator $\widehat{\mathbf{B}}$ has the following relationship*

$$\text{vec}(\widehat{\mathbf{B}}^\top) - \text{vec}(\mathbf{B}^\top) = (\mathbf{I}_p \otimes \boldsymbol{\Gamma}_r(0)^{-1})\bar{\mathbf{W}} + O_p(n^{-1}),$$

where

$$\bar{\mathbf{W}} = n^{-1} \sum_{i=1}^n \begin{pmatrix} \mathbf{W}_{1i} \\ \vdots \\ \mathbf{W}_{qi} \end{pmatrix} = n^{-1} \sum_{i=1}^n \mathbf{W}_i$$

with $\mathbf{W}_i = (\mathbf{q}_i + \mathbf{e}_i - \mathbf{B}\mathbf{e}_{i-1}^*) \otimes (\mathbf{z}_{i-1}^* - \boldsymbol{\mu}^* + \mathbf{e}_{i-1}^*) - \boldsymbol{\Psi}$ and $\boldsymbol{\Psi} = [\mathbf{I}_p \otimes (\mathbf{I}_r \otimes \boldsymbol{\Sigma}_e)] \text{vec}(\mathbf{B}^\top)$.

Proof: Define $\mathbf{B}_{.k}$ as a vector ($rp \times 1$) of coefficients associated with the k^{th} element of the vector $\mathbf{z}_t$, that is

$$z_{kt} = a_k + \mathbf{B}_{.k}^\top \mathbf{z}_{t-1}^* + q_{kt}.$$

Thus, we have that $\text{vec}(\mathbf{B}^\top) = (\mathbf{B}_{.1}^\top, \mathbf{B}_{.2}^\top, \dots, \mathbf{B}_{.p}^\top)^\top$ and the estimator of Theorem 1 for it can be written as $\text{vec}(\widehat{\mathbf{B}}) = (\widehat{\mathbf{B}}_{.1}^\top, \widehat{\mathbf{B}}_{.2}^\top, \dots, \widehat{\mathbf{B}}_{.p}^\top)^\top$, where $\widehat{\mathbf{B}}_{.k} = (\mathbf{S}\mathbf{z}_{t-1}^* - \mathbf{I} \otimes \boldsymbol{\Sigma}_e)^{-1} \mathbf{S}\mathbf{z}_{t-1}^* z_{kt}$ and $\mathbf{S}\mathbf{z}_{t-1}^* z_{kt} = n^{-1} \sum_{i=1}^n (\mathbf{Z}_{i-1}^* - \bar{\mathbf{Z}}_{t-1}^*) Z_{kt}$ for $k = 1, \dots, p$. Moreover, the model (2) may be rewritten in terms of the observed variables as

$$\begin{aligned} \mathbf{Z}_t &= \mathbf{a} + \mathbf{B}\mathbf{Z}_{t-1}^* + \boldsymbol{\vartheta}_t, \\ \boldsymbol{\vartheta}_t &= \mathbf{q}_t + \mathbf{e}_t - \mathbf{B}\mathbf{e}_{t-1}^*, \end{aligned} \tag{14}$$

and for the k^{th} element of $\mathbf{Z}_t$ we have

$$\begin{aligned} Z_{kt} &= a_k + \mathbf{B}_{.k}^\top \mathbf{Z}_{t-1}^* + \vartheta_{kt}, \\ \vartheta_{kt} &= q_{kt} + e_{kt} - \mathbf{B}_{.k}^\top \mathbf{e}_{t-1}^*. \end{aligned} \tag{15}$$

Then, it follows that

$$\mathbf{S}\mathbf{z}_{t-1}^* z_k = n^{-1} \sum_{i=1}^n (\mathbf{Z}_{i-1}^* - \bar{\mathbf{Z}}_{t-1}^*) (a_k + \mathbf{B}_{.k}^\top \mathbf{Z}_{i-1}^* + \vartheta_{ki}) = \mathbf{S}\mathbf{z}_{t-1}^* \mathbf{B}_{.k} + \mathbf{S}\mathbf{z}_{t-1}^* \vartheta_k,$$

where $\mathbf{S}_{\mathbf{Z}_{t-1}^* \vartheta_k} = n^{-1} \sum_{i=1}^n (\mathbf{Z}_{i-1}^* - \bar{\mathbf{Z}}_{t-1}^*) \vartheta_{ki} = n^{-1} \sum_{i=1}^n (\mathbf{z}_{i-1}^* - \boldsymbol{\mu}^* + \mathbf{e}_{i-1}^*) \vartheta_{ki} + O_p(n^{-1})$. Hence, denoting $\mathbf{S}_{\mathbf{z}_{t-1}^* \vartheta_k} = n^{-1} \sum_{i=1}^n (\mathbf{z}_{i-1}^* - \boldsymbol{\mu}^* + \mathbf{e}_{i-1}^*) \vartheta_{ki}$ we have that

$$\mathbf{S}_{\mathbf{Z}_{t-1}^* \mathbf{Z}_k} = (\mathbf{S}_{\mathbf{Z}_{t-1}^*} - \mathbf{I}_r \otimes \boldsymbol{\Sigma}_e) \mathbf{B}_{.k} + \mathbf{S}_{\mathbf{z}_{t-1}^* \vartheta_k} - \boldsymbol{\Psi}_k + O_p(n^{-1}),$$

with $\boldsymbol{\Psi}_k = -\mathbf{I}_r \otimes \boldsymbol{\Sigma}_e \mathbf{B}_{.k}$. As a result, we have

$$\widehat{\mathbf{B}}_{.k} = \mathbf{B}_{.k} + \Gamma_r^{-1}(0) \bar{\mathbf{W}}_k + O_p(n^{-1})$$

where $\bar{\mathbf{W}}_k = n^{-1} \sum_{i=1}^n \mathbf{W}_{ki}$ and $\mathbf{W}_{ki} = (\mathbf{z}_{i-1}^* - \boldsymbol{\mu}^* + \mathbf{e}_{i-1}^*) \vartheta_{ki} - \boldsymbol{\Psi}_k$. Hence, it follows that

$$\text{vec}(\widehat{\mathbf{B}}^\top) - \text{vec}(\mathbf{B}^\top) = (\mathbf{I}_p \otimes \Gamma_r(0)^{-1}) \bar{\mathbf{W}} + O_p(n^{-1}),$$

where

$$\bar{\mathbf{W}} = n^{-1} \sum_{i=1}^n \begin{pmatrix} \mathbf{W}_{1i} \\ \vdots \\ \mathbf{W}_{qi} \end{pmatrix} = n^{-1} \sum_{i=1}^n \mathbf{W}_i$$

with $\mathbf{W}_i = (\mathbf{q}_i + \mathbf{e}_i - \mathbf{B} \mathbf{e}_{i-1}^*) \otimes (\mathbf{z}_{i-1}^* - \boldsymbol{\mu}^* + \mathbf{e}_{i-1}^*) - \boldsymbol{\Psi}$ and $\boldsymbol{\Psi} = [\mathbf{I}_p \otimes (\mathbf{I}_r \otimes \boldsymbol{\Sigma}_e)] \text{vec}(\mathbf{B}^\top)$.

Proposition 2. *If $\mathbf{e}_t \sim \mathcal{N}(\mathbf{0}, \boldsymbol{\Sigma}_e)$ with $\boldsymbol{\Sigma}_e$ known and $E(q_{ij_1} q_{ij_2} q_{ij_3} q_{ij_4}) < \infty$ for all $j_1, j_2, j_3, j_4 \in \{1, \dots, p\}$, where q_{ij} is the j^{th} element of $\mathbf{q}_i$. The mean, $\bar{\mathbf{W}}$, of Proposition 1 has an asymptotic distribution given by*

$$\sqrt{n} \bar{\mathbf{W}} \xrightarrow{\mathcal{D}} \mathcal{N}(\mathbf{0}, \mathbf{T}_r),$$

where

$$\begin{aligned} \mathbf{T}_r &= \boldsymbol{\Sigma}_\vartheta \otimes \Gamma_r(0) + \boldsymbol{\Sigma}_\vartheta \otimes (\mathbf{I}_r \otimes \boldsymbol{\Sigma}_e) + \mathbf{B}^\top \otimes [\boldsymbol{\Sigma}_e \mathbf{B} (\mathbf{I}_r \otimes \boldsymbol{\Sigma}_e)] + \\ &\quad - \sum_{h=1}^r \left\{ (\mathbf{B}_h \boldsymbol{\Sigma}_e) \otimes \Gamma_r(h) + (\boldsymbol{\Sigma}_e \mathbf{B}_h^\top) \otimes \Gamma_r(-h) \right\} + \\ &\quad + \sum_{h=1-r}^{r-1} [\mathbf{B} (\mathbf{J}_{-h} \otimes \boldsymbol{\Sigma}_e) \mathbf{B}^\top] \otimes \Gamma_r(h). \end{aligned}$$

where $\mathbf{J}_l$ is a $(r \times r)$ matrix of zeros with one's in the $|l|^{\text{th}}$ diagonal above (below) the main diagonal if $l > 0$ ($l < 0$) and $\mathbf{J}_0$ is a $(r \times r)$ matrix of zeros.

Proof: Notice that the expectation of $\mathbf{W}_i$ is equal to zero for all i . Shumway and Stoffer (2000) state a central limit theorem to a univariate M-dependent sequence of random variables with mean zero. We say that a time series x_t is

M-dependent if the set of values $x_s, s \leq t$ is independent of the set of values $x_s, s \geq t + M + 1$ (Shumway and Stoffer, 2000, on pg. 66). Then, assuming that $E(q_{ij_1} q_{ij_2} q_{ij_3} q_{ij_4}) < \infty$ for all $j_1, j_2, j_3, j_4 \in \{1, \dots, p\}$ where q_{ij} is the j^{th} element of $\mathbf{q}_i$ and defining $\bar{x} = n^{-1} \sum_{i=1}^n x_i$, where $x_i = \boldsymbol{\delta}^\top \mathbf{W}_i$ we have that $E(x_i) = 0$, $\text{Cov}(x_i, x_{i-h}) = \boldsymbol{\delta}^\top \text{Cov}(\mathbf{W}_i, \mathbf{W}_{i-h}^\top) \boldsymbol{\delta} = \boldsymbol{\delta}^\top E(\mathbf{W}_i \mathbf{W}_{i-h}^\top) \boldsymbol{\delta}$ and

$$\begin{aligned} E(\mathbf{W}_i \mathbf{W}_{i-h}^\top) &= E[\mathbf{F}_{ih} \otimes (\mathbf{z}_{i-1}^* - \boldsymbol{\mu}^*)(\mathbf{z}_{i-h-1}^* - \boldsymbol{\mu}^*)^\top] + E[\mathbf{F}_{ih} \otimes \mathbf{e}_{i-1}^* \mathbf{e}_{i-h-1}^{*\top}] + \\ &+ E[\mathbf{F}_{ih} \otimes \mathbf{e}_{i-1}^* (\mathbf{z}_{i-h-1}^* - \boldsymbol{\mu}^*)^\top] + E[\mathbf{F}_{ih} \otimes (\mathbf{z}_{i-1}^* - \boldsymbol{\mu}^*) \mathbf{e}_{i-h-1}^{*\top}] - \\ &- \boldsymbol{\Psi} \boldsymbol{\Psi}^\top \end{aligned}$$

with $\mathbf{F}_{ih} = (\mathbf{q}_i + \mathbf{e}_i - \mathbf{B} \mathbf{e}_{i-1}^*)(\mathbf{q}_{i-h} + \mathbf{e}_{i-h} - \mathbf{B} \mathbf{e}_{i-h-1}^*)^\top$. Thus, using some matricial results and simple expectation rules we can solve these expectations as follows

$$\begin{aligned} E(\mathbf{W}_i \mathbf{W}_{i-h}^\top) &= \mathbf{0} \quad \text{for } |h| < r, \\ E(\mathbf{W}_i \mathbf{W}_{i-h}^\top) &= -(\mathbf{B}_r \boldsymbol{\Sigma}_e) \otimes \boldsymbol{\Gamma}_r(h) \quad \text{for } h = r, \\ E(\mathbf{W}_i \mathbf{W}_{i-h}^\top) &= -(\boldsymbol{\Sigma}_e \mathbf{B}_{|r|}^\top) \otimes \boldsymbol{\Gamma}_r(h) \quad \text{for } h = -r, \\ E(\mathbf{W}_i \mathbf{W}_{i-h}^\top) &= [\mathbf{B}(\mathbf{J}_{-h} \otimes \boldsymbol{\Sigma}_e) \mathbf{B}^\top] \otimes \boldsymbol{\Gamma}_r(h) - (\mathbf{B}_h \boldsymbol{\Sigma}_e) \otimes \boldsymbol{\Gamma}_r(h) \quad \text{for } h = 1, \dots, r-1, \\ E(\mathbf{W}_i \mathbf{W}_{i-h}^\top) &= [\mathbf{B}(\mathbf{J}_{-h} \otimes \boldsymbol{\Sigma}_e) \mathbf{B}^\top] \otimes \boldsymbol{\Gamma}_r(h) - (\boldsymbol{\Sigma}_e \mathbf{B}_{|h|}^\top) \otimes \boldsymbol{\Gamma}_r(h) \quad \text{for } h = -1, \dots, 1-r, \\ E(\mathbf{W}_i \mathbf{W}_{i-h}^\top) &= \boldsymbol{\Sigma}_\vartheta \otimes \boldsymbol{\Gamma}_r(0) + \boldsymbol{\Sigma}_\vartheta \otimes (\mathbf{I}_r \otimes \boldsymbol{\Sigma}_e) + \mathbf{B}^\top \otimes [\boldsymbol{\Sigma}_e \mathbf{B}(\mathbf{I}_r \otimes \boldsymbol{\Sigma}_e)] \quad \text{for } h = 0, \end{aligned}$$

where $\mathbf{J}_l$ is a $(r \times r)$ matrix of zeros with one's in the $|l|^{th}$ diagonal above (below) the main diagonal if $l > 0$ ($l < 0$) and $\mathbf{J}_0$ is a $(r \times r)$ matrix of zeros. That is, $x_1, \dots, x_n$ is a strictly M-dependent sequence of random variables with mean zero (where $M = r$) and, therefore, we can use the result stated in Shumway and Stoffer (2000), which says that

$$\sqrt{n} \bar{x} \xrightarrow{\mathcal{D}} \mathcal{N}(0, V_r)$$

where

$$V_r = \sum_{h=-r}^r \text{Cov}(\boldsymbol{\delta}^\top \mathbf{W}_i, \boldsymbol{\delta}^\top \mathbf{W}_{i-h}) = \boldsymbol{\delta}^\top \mathbf{T}_r \boldsymbol{\delta}$$

with

$$\begin{aligned}
\mathbf{T}_r &= \boldsymbol{\Sigma}_\vartheta \otimes \boldsymbol{\Gamma}_r(0) + \boldsymbol{\Sigma}_\vartheta \otimes (\mathbf{I}_r \otimes \boldsymbol{\Sigma}_e) + \mathbf{B}^\top \otimes [\boldsymbol{\Sigma}_e \mathbf{B} (\mathbf{I}_r \otimes \boldsymbol{\Sigma}_e)] + \\
&\quad - \sum_{h=1}^r \left\{ (\mathbf{B}_h \boldsymbol{\Sigma}_e) \otimes \boldsymbol{\Gamma}_r(h) + (\boldsymbol{\Sigma}_e \mathbf{B}_h^\top) \otimes \boldsymbol{\Gamma}_r(-h) \right\} + \\
&\quad + \sum_{h=1-r}^{r-1} [\mathbf{B}(\mathbf{J}_{-h} \otimes \boldsymbol{\Sigma}_e) \mathbf{B}^\top] \otimes \boldsymbol{\Gamma}_r(h).
\end{aligned}$$

As $\sqrt{n}\boldsymbol{\delta}^\top \bar{\mathbf{W}}$ is asymptotically normally distributed for all $\boldsymbol{\delta} \neq \mathbf{0}_r$ then, by the Cramer-Wold device (see Theorem 10.4.5 on page 336 in Athreya and Lahiri, 2006), we have that

$$\sqrt{n}\bar{\mathbf{W}} \xrightarrow{\mathcal{D}} \mathcal{N}(\mathbf{0}, \mathbf{T}_r).$$

Then, by the Propositions 1 and 2, the prove of Theorem 2 follows

$$\sqrt{n}(\text{vec}(\hat{\mathbf{B}}^\top) - \text{vec}(\mathbf{B}^\top)) \xrightarrow{\mathcal{D}} \mathcal{N}(\mathbf{0}, [\mathbf{I}_p \otimes \boldsymbol{\Gamma}_r(0)^{-1}] \mathbf{T}_r [\mathbf{I}_p \otimes \boldsymbol{\Gamma}_r(0)^{-1}]).$$
